**Keywords:** introduced species; tidal habitats; marshland; fish assemblages; Spain

The distribution and apparent habitat preferences of the common mummichog (*Fundulus heteroclitus*) in southwestern Spain were examined during summer-fall 1996. This introduced species was more or less continuously distributed along the Atlantic coast of Spain, being more abundant in sites near the coastline (usually < 10 km inland), mainly in four extensive marshes. The species preferred marsh-related mesohabitats, such as salt lagoons, salt marsh fish ponds and marsh channels, both natural and man-modified. *F. heteroclitus* was mostly found at salinities > 25. It was the most frequently captured fish species, occurring at 81 of the 272 sites sampled; their frequency of occurrence was almost twice that of the second ranked species (*Gambusia holbrooki*). However in over 80 % of cases, *F. heteroclitus* was found alone or with only one sympatric fish species, which usually belonged to a group composed of *Gobius niger*, mugilids, *Anguilla anguilla*, *Blennius* sp., *Lebias ibera*, *Pomatoschistus* sp. and *Dicentrarchus labrax*. Finally, we discuss the origin and dispersal of mummichog in the Iberian peninsula and the potential effects of this species on native fish populations.
Introduction

The mummichog, *Fundulus heteroclitus*, is an exceptionally wide ranging cyprinodontid fish. It naturally occurs along the east coast of North America from south-western Newfoundland to northeastern Florida. This species is ubiquitous in North American East Coast salt marshes, being mostly found in sheltered coastal waters. Although occasionally it inhabits freshwater habitats, the species is best known from the tidal salt marsh, a fluctuating physical environment for which mummichogs are well adapted due to considerable plasticity in their ecological requirements (Kneib, 1986).

The first records of *F. heteroclitus* in the Iberian Peninsula are dated between 1973-1976 (Hernando, 1975; Coelho et al., 1976). However, the precise date and location of the species’ introduction still remains unclear. Although there have been studies describing its life-history pattern (Arias & Drake, 1986; Drake et al., 1987; Fernández-Delgado, 1989) and density (Arias & Drake, 1987, 1989) little is known about the role of *F. heteroclitus* in this new European habitat. The introduction of exotic species can have a negative effect on the functioning of native ecosystems (Dowling & Childs, 1992; Barlow et al., 1987; Richardson & Whoriskey, 1992). It is suspected that mummichogs may have already negatively affected some native endemic species like the endangered *Lebias ibera*.

This study describes the detailed distribution and abundance of *F. heteroclitus* along the coast of southwestern Spain. Also we document their habitat preferences, including the composition of the fish assemblages found in those habitats. Finally, we discuss the potential causes of the observed pattern of mummichog distribution and the effects of this species on native fish populations.

Methods

Study area

This study was carried out in an area near the coast in the provinces of Huelva, Sevilla and Cádiz (southwestern Spain) (Figure1). Doñana National Park has been excluded because it was previously studied by Fernández-Delgado et al. (1994).

A complete description of the study area can be found in Fernández-Palacios et al., (1988). The area can be divided in two sectors, the postorogenic one, covering most
of the northwestern part of the area, and the preorogenic surrounding the Gibraltar strait (see the limit between both sectors in Figure 1). The preorogenic is very heterogeneous (made of mostly by Jurassic lymes and sandstones), and consists of high reliefs, capes and cliffs. The postorogenic is more homogeneous, composed of Quaternary biogenic chalk and sands, that form flat lands, small bays and long sandy stretches of beach; a morphology that obstructs the drainage of fluvial currents and encourages the formation of marshes and coastal dunes.

Tidal range in the Atlantic sectors fluctuates between 2.5-3 m (see Figure 2), while in the Mediterranean sector (n 9, Figure 2) it is always less than 0.8 m. This difference, along with the intense westerly winds, generates a strong sea current towards the Mediterranean, and also determines the extent of tidal habitat and marsh formation at the river mouths. As a consequence, marshes are much more abundant and extensive along the Atlantic coast than along the Mediterranean, specially in the postorogenic sector (see Figure 1)

The climate in the area is Mediterranean (semi)humid with mild winters. The average temperature is usually between 10-12° C in winter and about 23-25° C in summer. The rainfall varies more than temperature. In sector 1 (Figure 2) the annual average rainfall is 500-600 mm, while in sectors 8 and 9 it is higher than 800 mm.

Field sampling
Between August and December of 1996, we sampled 272 sites from potential sites identified on 1:50.000 maps (National Grid of Spain). These included all the water bodies near the coast and/or under tidal influence or placed in low flat lands (usually below 100 m of altitude). At each sampling site, fishes were collected from a 100 m reach.

Each sampling site was classified into one of the following habitat categories: creek (low order streams, usually less than 3rd order), stream (≥ 3rd order), stream pool (isolated pools in drying streams), man-made channel, pond (small size lakes, usually less than 2 ha), natural marsh, modified marsh (slightly disturbed marshes, with few symptoms of human intervention), altered marsh (moderate to highly disturbed marshes, with clear symptoms of human impacts), salt marsh fish pond (traditional extensive fish culture), marsh salt mine, fish farm (intensive fish culture) and tidal lagoon.
Different types of sampling gear used in this study included: trawls, fyke nets (prawn traps) 2 mm mesh size (2 m length, 0.1 m entrance diameter), minnow traps (Harrison et al., 1986) (0.5 m length, 0.03 m entrance diameter) and quadrangular (40 x 40 cm) hand nets. The selection of the type and number of fishing gears was decided *in situ* depending on the depth and extension of the water body, the type of aquatic vegetation and the water turbidity. Minnow traps were used in all cases. The active fishing methods (trawls and hand nets) were mainly used to trap species other than mummichog. In this case the catches were only identified and not counted.

The passive fishing methods (fyke nets and minnow traps) were set for roughly 24 hours. Once the sampling was finished, the species caught were identified and the total number of individuals in each of them was counted. The results of this sampling are expressed as catches per unit effort (c.p.u.e.), 1 unit being a passive trap in place for 24 h. To minimize the possible differences in relative abundance due to the different efficiencies of the traps, we used a relative abundance index (RAI) for mummichog following the criteria:

\[
\text{if c.p.u.e. } \leq 4 \implies \text{RAI} = 1 \\
\text{if c.p.u.e. } 4.1-8 \implies \text{RAI} = 2 \\
\text{if c.p.u.e. } 8.1-12 \implies \text{RAI} = 3 \\
\text{if c.p.u.e. } 12.1-16 \implies \text{RAI} = 4 \\
\text{if c.p.u.e. } > 16 \implies \text{RAI} = 5
\]

**Data analysis**

To evaluate the relative abundance of the species along its distribution area, the study area was divided into 18 sectors of a similar extent and the cumulative RAI was calculated for each one of them.

To measure habitat and salinity preferences of mummichog and other fish species, we used the Vanderploeg and Scavia electivity index \((E_i^*)\) (Lechowicz, 1982):

\[
E_i^* = \frac{W_i - (1/n)}{W_i + (1/n)} \\
W_i = \frac{r_i}{p_i} / \left( \sum \frac{r_i}{p_i} \right)
\]
\[ r_i = \text{proportion of “used” habitat } i \text{ or salinity category } i \]
\[ p_i = \text{proportion of “available” habitat } i \text{ or salinity category } i \text{ in the environment} \]
\[ n = \text{number of habitat types or salinity categories} \]

This index \((E_i^*)\) has a value of zero for random use of the variable of interest and a possible range between 1 (maximum preference) and -1 (total rejection).

To analyse the relationship between the mummichog and the rest of the fish species captured we have calculated \(E_i^*\). Here the “used” variable \(i\) was the frequency of coexistence of the species \(i\) with \(F. \text{heteroclitus}\), and the “available” variable \(i\) was the absolute frequency of appearance of that species.

To group the different fish species found in the study area according to their habitat preferences, a Principal Component Analysis (PCA) was done on a “habitat type x fish species” matrix, where each \(a_{ij}\) was the habitat \(i\) electivity index \((E_i^*)\) of species \(j\). Thus, species with similar habitat preferences should appear grouped.

To calculate the mummichog preference of coexistence with other fish species we have computed the residuals of the regression line between the absolute frequency and the frequency of coexistence with \(F. \text{heteroclitus}\) of each species. Thus, those species with higher residual absolute value can be considered as “preferred” or “rejected” by \(F. \text{heteroclitus}\), independently of their absolute frequency of appearance.

**Result**

**Distribution**

\(F. \text{heteroclitus}\) was found, more or less continuously, along the Southern Spain Atlantic coast, from the mouth of the Guadiana River (Huelva) to the marshes of the Barbate River (Figure 1). \(F. \text{heteroclitus}\) was captured in 81 of 270 sites sampled. The species tended to be found in four main areas (Fig. 1) coinciding, in general, with extensive marshes. \(F. \text{heteroclitus}\) was never found in sites far (usually less than 10 km, maximum 18 km) from the coast line.
Habitat preferences

The species was found in 11 of the 12 habitat categories established (Table 1), and preferred marsh-related habitats, specially salt lagoons, salt marsh fish ponds, marshes (both natural and man-modified), fish farms and tidal lagoons. Mummichogs were not found in inland water bodies (stream pools, man-made channels, ponds, creeks and streams) (Table 1). Thus, *F. heteroclitus* were restricted to the saline habitats, usually with salinity values higher than 25 (Table 2).

To evaluate the distribution pattern of the relative abundance of *F. heteroclitus* along its distribution, the sum of the RAI values per sector (cumulative RAI) into which the study area was divided is shown in Figure 2a and 2b.

The RAI values differed significantly between sectors (Kruskal-Wallis statistic=14.8, P<0.022). Along a gradient of distance from the coast, significantly more mummichogs were captured in the coastal sector than in the inland one (Mann-Whitney test: Z=2.67, P=0.0075) (Figure 2b). Sector 1 contained the extensive marshes of the lower Guadiana River. In contrast, sectors 4, 8 and 9 did not contain any marsh areas, except the small Palmones marshes in sector 9.

Fish species assemblages

A total of 21 fish species was captured (the mugilids were considered as one taxon, although 5 species were identified) (Table 3). *F. heteroclitus* was the species captured most frequently (81), almost twice as much as the species that ranked second (*G. holbrooki*: 41 times); both are exotic introductions to the Iberian Peninsula. Other species were divided into two groups: those associated with *F. heteroclitus* (positive $E_{i}^{*}$ values) and those that did not coexist with it (negative $E_{i}^{*}$ values) (Table 3).

*F. heteroclitus* appeared alone or with only one other species of fish in over 80% of cases. Mummichog was never caught with four or more species. However, in some salt marsh fish ponds the mummichog coexisted with 10 fish species (Arias & Drake, 1987).

According to their habitat preferences five groups of species were obtained following the PCA of the “species x $E_{i}^{*}$ index” matrix, based on their correlations with both PC1 and PC2 [Figure 3(a)]. Each group of species could be assigned to a particular habitat [Figure 3(b)]. *F. heteroclitus* was clearly isolated from the remaining groups. As expected, *F. heteroclitus* preferred salt marsh-related habitats. The group composed of
Gobius niger (GN), Mugilids (MM), Anguilla anguilla (AA), Blennius sp. (BL), Lebias iberia (LI), Pomatoschistus sp. (PS) and Dicentrarchus labrax (DL) was not significantly correlated with any PC axis. This group was not directly related with any of the habitat types observed in the PCA and can coexist with *F. heteroclitus*.

The distribution of the residuals in relation to the absolute frequency of occurrence of each species (Figure 4, see Methods), points out positive associations between mummichogs and mugilids, *G. niger* and *A. anguilla*. The remaining species potentially coexisting with *F. heteroclitus* (*Pomatoschistus* sp., *L. iberia* and *Blennius* sp.), did not display either a positive or negative association with this species (Figure 4).

**Discussion**

*On the origin and dispersal of F. heteroclitus in the Iberian Peninsula*

The taxonomic status and origin of *F. heteroclitus* in the Iberian Peninsula has been a long debated and controversial subject since the first record of the species in 1973 (Hernando, 1975; Coelho *et al*., 1976; Gómez-Caruana *et al*., 1984; 1987; Fernández-Delgado *et al*., 1986; Bernardi *et al*., 1995). It seems that the species was originally introduced in the marshes of the province of Huelva in the early seventies, with individuals coming from the northern population (Nova Scotia) of its natural distribution area (Bernardi *et al*., 1995). This is the only known mummichog population outside of its natural habitat. However, the way in which this introduction was accomplished remains unknown. It is not possible that the mummichog could have arrived in Spain accidentally with the first red swamp crayfish (*Procambarus clarkii*) introductions as has been hypothesized, because this crustacean was delivered in June 1973 in the Badajoz province (150 km from the nearest point of its actual distribution). It was not until 1974 when the red swamp crayfish was introduced in the Guadalquivir marshes (Delibes & Adrián, 1987). Even before those introductions Hernando (1975) captured adult mummichogs, both in the Guadalquivir (March 1973) and Guadiana marshes (April 1974).

*F. heteroclitus* was recorded in March 1976 on the Portuguese side of the Guadiana marshes (Coelho, et al. 1976), in the Cádiz Bay marshland in the summer of 1983 (Arias & Drake, 1986) and in the Barbate marshes in November 1996 (this study), where the species is known approximately from 1993 (local fishermen, com. pers.). It
seems that mummichogs quickly colonized the Guadalquivir and Guadiana marshes (i.e. in a northwestern direction). However the southeastern dispersion of this species was much slower and apparently this process has stopped at the Barbate marshes.

Locally, Arias and Drake (1989) observed that the mummichog quickly colonized the coastal fringe of the Cádiz bay salt marshes. However the inland dispersion of the species in these marshes seemed to be much slower. Six years after the first record of its appearance in this area, the mummichogs still have not colonized many habitats.

Where they are endemic, *F. heteroclitus* seems to display a very small home range and usually inhabits the same habitat patch for extensive time periods (Lotrich, 1975). Thus, the trigger to leave a site and the way certain individuals arrive at a new location - the precise dispersal mechanism of this species - is unknown. It is possible that this colonization process could be facilitated by man, through direct transport of individuals from one site to another. Also, under natural circumstances, the dispersal velocity could be related to some coastal characteristics, as will be discussed later.

_Habitat preferencies and actual distribution_

Doadrio et al. (1991) fix the distribution of *F. heteroclitus* at the marshes of the Cádiz Bay. With this work the distribution area of *F. heteroclitus* in the Iberian Peninsula is extended to the Barbate marshes. The species has not been found in any of the sites sampled in the Mediterranean coast, including 76 sites sampled in the Granada and Almeria provinces (Fernández-Delgado et al., 1997), the River Ebro delta marshes and the rest of the Catalonian coast (García-Berthou & Moreno-Amich, 1991) nor in the most southwesternly portion of the Portuguese coast (Beja, 1991). The reasons for such a distribution can be related to the habitat preferences displayed by mummichogs, i.e., salt marsh areas with some human influence. *F. heteroclitus* exhibits a life history closely linked to the intertidal salt marsh (Kneib, 1984), but with very few microhabitat preferences (Weisberg, 1986). Typical marsh areas, as those previously mentioned, are almost lacking from the Southern Spain Mediterranean coast and from most southwestern Portugal.

The maximum *F. heteroclitus* relative abundance (up to 63 individuals trap$^{-1}$ hour$^{-1}$) was found in the largest areas of salt marsh (Huelva and Cádiz marshes). Also *F. heteroclitus* was the species that inhabited more types of habitats, 11 of 12, lacking or being very scarce only from those with unidirectional flow like streams and man-made
channels. These freshwater habitats tend to be inland, which may help to explain the low density value obtained for those sites far from the coastline. The lowest abundance values found for *F. heteroclitus* could be because this species had recently colonized the area, and/or that a suitable habitat did not exist for it.

In the Atlantic coast of the Iberian Peninsula *F. heteroclitus* inhabited a wide range of salinities, but preferred the most saline sites, usually above 25. However, according to Weisberg (1986) *F. heteroclitus* is unaffected by salinity and has been reported in freshwater habitats (Rozas & Odum, 1987). Thus *F. heteroclitus* may be absent from many freshwater water bodies independently of the water salt content but due to other factors, such as the lack of tidal fluctuations and the presence of natural or man-made barriers.

*Potential effects of mummichog on native fish populations*

*F. heteroclitus* was the most widespread species and probably, also the most abundant of all the fish captured. It points out the great success of the species in this new habitats. This could be due to many factors such as the capacity to survive in water where the salinity range is large (0-128) (Feldmeth & Waggoner, 1972) and the high productivity that these tidal habitats (29.8% of the habitats sampled were tidal marshes) (Valiela *et al.*, 1977; Meredith & Lotrich, 1979; Arias & Drake, 1989). These characteristics give *F. heteroclitus* a great capacity to colonize different types of habitats, including those very marginal not used almost for any other species. In only 19.7% of the sites sampled where mummichog was found, two or more species were found as well, which suggests that the mummichog is occupying an extreme habitat -an empty niche-, not occupied by any of the native species previously. On the other hand, if *F. heteroclitus* were not filling an otherwise empty niche, it seems obvious that a species with such an expansion capacity, along with its productivity, must have a great influence on the local fish populations. *F. heteroclitus* is clearly the dominant species in these marsh habitats under tidal influence, at least for fish within its size range (Arias & Drake, 1987). Up to day it is not known which species, if any, have been outcompeted by *F. heteroclitus*.

Arias & Drake (1987) observed high densities of *F. heteroclitus* in the salt marshes of Cádiz Bay, where maximum biomass was 2049 Kg ha⁻¹. In spite of this, it seemed that this species did not affect the productivity of commercial fish species cultivated in those marshes. Notwithstanding, Arias & Drake (1987, 1989) proposed that
this extremely high productivity may be affecting the energy fluxes in these ecosystems, at least removing part of the trophic resources that might be consumed by other fish species.

If mummichog were outcompeting other species, the mechanisms of this potential exclusion have not been directly evaluated and remain unknown. However, direct predation does not seem to be one of them because *F. heteroclitus* consumes only invertebrates and plants in the study area (Hernando, 1975; Arias & Drake, 1986). Also, the competition for food does not seem to be a decisive factor due to the enormous productivity of the areas where it is found. So, the competition for space could be the best explanation, if any, for this apparent segregation observed for mummichog and other fish species in the study area.

It is rather difficult to evaluate the precise ecological consequences of the mummichog introduction in southern Iberia, especially due to the fact that the original environmental conditions existing in the area where it was introduced are unknown. But, it is probable that some effects may have been negative, e. g. for the local fish fauna that might have been displaced, as well as economic losses in traditional prawn fishing, heavily consumed by mummichog (Arias & Drake, 1986). On the other hand *F. heteroclitus* is consumed in large quantities by very important commercial fish species, such as large *Sparus aurata* and *Dicentrarchus labrax* (A. Arias, personal communication). Also, mummichog seems to have a positive effect on some endangered birds, like spoonbills (*Platalea leucorodia*), storks (*Ciconia ciconia*) and several ardeids (*Ardea* spp, *Egretta garzetta*, etc.) (C. Delecourt, personal communication). Clearly, the potential impacts of *F. heteroclitus* in the environmental rich tidal wetlands of southwestern Spain should be further investigated.
Acknowledgements
This study was financially sponsored by the Consejería de Medio Ambiente (Autonomous Government of Andalusia) under the “Plan de recuperación del fartet (Lebias ibera) en Andalucía”. P. Drake, R. T. Kneib and two anonymous referees made very valuable suggestions and comments to an earlier version of the manuscript.
